MEMORANDUM FOR: The Director of Central Intelligence

SUBJECT : Chapter IX of SECRET Soviet Manual on Atomic
Weapons and Antiatomic Protection

1. Enclosed is a verbatim translation of Chapter IX of a Soviet SECRET document entitled "A Guide to the Combat Characteristics of Atomic Weapons and to the Means of Antiatomic Protection". It was published in 1957 by the Ministry of Defense, USSR.

2. For convenience of reference by USIB agencies, the codeword IRONBARK has been assigned to this series of TOP SECRET CSDB reports containing documentary Soviet material. The word IRONBARK is classified CONFIDENTIAL and is to be used only among persons authorized to read and handle this material.

3. In the interests of protecting our source, IRONBARK material should be handled on a need-to-know basis within your office. Requests for extra copies of this report or for utilization of any part of this document in any other form should be addressed to the originating office.

COUNTRY : USSR

SUBJECT : Soviet Manual on Atomic Weapons and
Antiatomic Protection (Chapter IX)

DATE OF INFO : 1957

APPRAISAL OF
CONTENT : Documentary

SOURCE : A reliable source (B).

Following is a verbatim translation of Chapter IX of a Soviet SECRET document titled "A Guide to the Combat Characteristics of Atomic Weapons and to the Means of Antiatomic Protection." This manual was published in 1957 by the USSR Ministry of Defense as a replacement for a similar 1954 manual (CSDB-35586), and is referenced in the Information Collection of the Artillery (cf. CSDB-3/649,649). It had not been superseded as of late 1961. A similar, more general document was also published by the 6th Directorate of the Ministry of Defense in 1959 (CSDB-3/649,686).

Chapter IX

Engineer Means of Protection from Atomic Weapons

32. Requirements for the Construction of Installations

Which Will Ensure Protection from Atomic Weapons

Defensive installations, constructed for protection of personnel, weapons, materiel and equipment, must ensure protection both from ordinary means of destruction (aerial bombs and projectiles) and from atomic weapons.

All the construction elements of the installations (barrier works, entrances, apertures and the like) must be of uniform strength and capable of bearing the load exerted on them by a given pressure in front of the shock wave of an atomic burst.

The external elements of the installations must not catch fire from the impingement of thermal radiation. The protective thickness of installations is chosen on the basis of the requirements for the protection of personnel in the installations from injury from penetrating radiation at those distances from the place of an atomic burst at which they are protected from the shock wave.

The construction of entrances, gun ports, and filter-ventilation systems must preclude the possibility of the shock wave or radioactive materials penetrating into the installation.

33. Structural Strength and Protective Properties of Defense

Installations Trenches, Dugouts and Connecting Trenches

The simplest installations - trenches, connecting trenches and dugouts (Figure 118) - possess significant protective properties: they protect against thermal radiation, reduce the shock wave pressure, and attenuate the penetrating radiation dose.

50X1-HUM

~~SECRET~~

~~SECRET~~

50X1-HUM

IRONBARK

CSDB-3/650,080

Trenches, connecting trenches and dugouts are fully covered at the first opportunity. Trenches and connecting trenches must have smooth outlines in the design.

In unstable soils (sand, fine sand, and sandy loam) the simplest shelters are made, as a rule, with revetments of poles, brush, slabs, boards, canes and other materials. Special attention is given to the strength of support fastenings. Supports are driven into the ground to a depth of not less than 0.5 meter. In soft ground, and also in cases where supports cannot be driven to the desired depth, cross bars are placed flush with the ground between them. The upper ends of the supports are fastened with guy wires attached to anchor pickets located 2.5 to 3 meters from the top of the revetment.

Figure 118. Trenches

~~SECRET~~

~~SECRET~~

50X1-HUM

IRONBARK

CSDB-3/650,080

In order to increase the fire resistance of the revetted slopes of trenches and connecting trenches, especially at points of contact with the covered installation, they are covered with earth. Antifire gaps 1 to 2 meters wide and spaced every 40 to 50 meters are left in revetted slopes of great length.

Trenches and connecting trenches without revetted slopes, constructed in average soil, do not sustain damage at distances from the center (ground zero) of an atomic burst where the shock wave pressure, at the surface of the earth, is 0.3kg/cm^2 or less. At pressures of 0.3 to 0.5kg/cm^2 such trenches sustain slight damage, that is, damage which has practically no effect on their further military use.

Trenches with revetted slopes survive pressures of less than 0.5kg/cm^2 ; they sustain slight damage at pressures of 0.5 to 1.2kg/cm^2 .

Trenches and connecting trenches, as well as dugouts, when situated perpendicularly to the direction of shock wave movement, ensure protection from the impact of the shock wave pressure head, and from the direct impact of thermal radiation, and they reduce the penetrating radiation dose in an atomic air burst by 5 to 15 times.

The minimum distances from the center (ground zero) of a burst at which trenches (dugouts, connecting trenches) can ensure protection of personnel, are:

- with bursts of low yield warheads - about 0.9km;
- with bursts of medium yield warheads - about 1.4km.

Covered Sectors of Trenches (Connecting Trenches)

and Covered Slit Trenches

Covered sectors of trenches, connecting trenches and slit trenches may be made of logs, fascines, and may also have the form of wattle, earthen arches or arches of elongated sand bags (Figure 119). The slopes of the covered sectors of trenches, dug in soft or average soil, must be covered.

-5-

50X1-HUM

~~SECRET~~

~~SECRET~~

50X1-HUM

IRONBARK

CSDB-3/650,080

In winter time the covered sectors of trenches, connecting trenches and slit trenches may be made of snow, ice or frozen ground over a form made of wattle or fascines.

The covered sectors of trenches do not suffer damage at distances from the center (ground zero) of an atomic burst where the shock wave pressure, at the earth's surface, is less than 0.8kg/cm^2 . At pressures of 0.8 to 1.2kg/cm^2 they sustain slight damage.

Covered slit trenches do not suffer damage at pressures less than 1.0kg/cm^2 , but they sustain slight damage at pressures of 1 to 1.5kg/cm^2 .

 - 3. Brushwood, canes
 - 4. Stakes, d = 10 to 12cm at intervals of 50cm
 - 5. Drain-off channel

Covered portions of trenches and covered slit trenches completely protect personnel from thermal radiation and reduce the penetrating radiation dose by 25 to 50 times.

The minimum distances from the center (ground zero) of a burst, at which the covered portions of trenches (connecting trenches) and covered slit trenches ensure protection of personnel, are:

- with bursts of small yield warheads - about 0.7km;
- with bursts of medium yield warheads - about 1.2km.

Dugout Shelters

Dugout shelters are usually constructed for 4 to 8 men. Dugout frames are made of logs, poles, slabs, and also of reinforced concrete sections (blocks) or sections of corrugated steel (Figures 120 to 123).

SECRET

IRONBARK

The protective soil cover over dugouts must be not less than 100cm deep to ensure reduction of the penetrating radiation dose by 200 to 400 times. The entrances to dugouts are equipped with light-type protective doors.

The structurally strongest dugouts are made of reinforced concrete sections and corrugated steel; the least strong with revetted slopes made of poles and a cover made of logs. On the average, dugouts do not suffer damage from shock wave pressures at ground level less than $1.2\text{kg}/\text{cm}^2$. They sustain light damage from pressures of 1.2 to $2\text{kg}/\text{cm}^2$.

Dugouts of the construction cited above ensure protection of personnel at a distance of about 0.5km from ground zero of the burst of a low-yield atomic bomb and at a distance of about 0.8km from ground zero of the burst of a medium-yield bomb.

Light-Type Shelters

The light-type shelter is usually constructed by means of excavation. The frames of pit shelters are made of timbered elements in the form of frames, panels and blocks, and of reinforced concrete sections and corrugated steel sections (Figures 124, 125).

The soil thickness covering a light-type pit shelter must be no less than 160cm to ensure a 2000 to 3000 times reduction in the penetrating radiation dose. Entrances to the shelter are equipped with heavy-type protective doors, air intake openings and chimneys with anti-blast valves or gravel shock absorbers; chimney openings are fitted with hermetic valves closed by hand.

The structurally strongest shelter is made of frame blocks and reinforced concrete sections; the least strong shelter is made with frames in the form of a disjointed contour (v vide nezamknutogo kontura) (from sloping revetments made of poles).

The following data describe the average structural strength of light-type shelters. The installations do not suffer damage at shock wave pressures less than $1.0\text{kg}/\text{cm}^2$ at ground level, but at pressures of 1.0 to $3.0\text{kg}/\text{cm}^2$ they suffer light damage.

Light-type shelters of the construction given above protect personnel at a distance of 0.4km from the center of a surface or from ground zero of a low air burst of a low-yield atomic bomb and at a distance of 0.6km with a burst of a medium-yield bomb.

Troops can remain in hermetically sealed shelters equipped with filter-ventilating systems when the terrain and air are contaminated with toxic and radioactive materials.

The shelter is made in the form of a pit connected to the gun site by a ramp. If materials and time are available the position is made with a cover of logs. The entrance to the shelter is covered with joined panels made of beams (logs).

Shelters are constructed for guns firing from concealed positions so that the gun is covered to the upper edge of the shield.

Dugouts for antiaircraft guns, recoilless weapons and mortars are dug to a depth which does not interfere with firing.

Dugouts are built for the concealment of crews.

The location of dugouts relative to gun sites depends on the protective properties of the terrain and the expenditure of the minimum amount of time for occupying them on receipt of the warning signal of the danger of an atomic attack.

Slit trenches with recesses are built for ammunition. Sectors of slit trenches with recesses are covered (and if time permits, the whole slit trench is covered).

Trenches for guns, rocket launchers and mortars are shown in Figures 128 to 132.

Tanks, assault guns and armored personnel carriers in shelters are not tossed about by the shock wave, as a result of which the radius of the zones of severe and moderate damage to vehicles is diminished. Emplacements protect armored equipment to a lesser degree, since damage to the turret and gun is not prevented.

The protective properties of emplacements and shelters are described by the data given in Table 136.

Table 136

Concealed Positions for Ammunition, Fuel,Lubricants and Rear Area Equipment

Concealed positions for the preservation of ammunition, fuel, lubricants and rear area equipment are built if there are no natural shelters (ravines, pits, depressions).

Vaults (Figure 136) or pit-type shelters (Figure 137) are excavated for storing ammunition.

Pits are excavated for storing fuel and lubricants in containers, barrels and cans. When materials are available, the pits are covered.

It is recommended that large containers with fuel be buried and covered with a layer of earth. It is necessary to construct wooden

Shelters at Water Supply Points

At water supply points shelters are constructed:

- for wells, shafts and pump gear;
- for materials used for purification and storage of water;
- for personnel and means of transporting water.

Shelters for well shafts and pumps are shown in Figure 138. Pits, niches and covered slit trenches ensure the protection of well shafts, drilled wells, and pumping gear mounted on them from bursts of atomic weapons of medium yield at distances of 0.4 to 0.6km, and from small-yield weapons at distances of 0.25 to 0.4km.

The protection of drilled wells, set up in dugouts, is ensured from bursts of atomic weapons of medium yield at distances of 0.3 to 0.35km and from weapons of low yield at distances of about 0.2km.

Water purification facilities, mounted on vehicles, are placed in shelters of the pit type and portable facilities are placed in trenches or covered slit trenches.

Pits are prepared for the cover of authorized water storage equipment.

It is necessary to cover water tanks (type RYe-6000) with canvas in order to avoid radioactive fallout.

34. Protective Measures Against Shock Wave Penetration into Installations*

Shock Wave Penetration into installations through doors, air vents, gun ports, and other apertures may lead to destruction of the garrison and damage to the internal equipment of field defense installations even at distances from the center (ground zero) of an atomic burst where the protective features of the installations do not suffer real damage. Therefore special attention must be paid to the protection of apertures through which the shock wave may penetrate.

Note: * The protection of installations against the penetration of radioactive materials is ensured by measures carried out by antichemical defense and is not considered in this Guide.

IRONBARKProtection of Entrances and Gun Ports

Protective doors are used (in dugouts, shelters, covered machine gun and observation installations) for the protection of field defense installations against the penetration of the shock wave through entrances. Detachable panels are used in covered trenches.

Depending on the construction of the installation, the type of entrance and the availability of materials, protective doors may be made of wood, metal, or reinforced concrete. Metal or reinforced concrete doors are used in especially important underground or reinforced concrete installations. In addition, metal doors may be used in installations made of assembled reinforced concrete sections. Wooden doors are used in the majority of field defense installations (Figures 140, 141).

Protection of Ventilation Apertures and Chimneys

In order to protect ventilation apertures and chimneys against shock wave penetration the following are used:

- gravel filter-shock absorber;
- filter-shock absorbers combined with valve cut-off for the shock wave;
- antiblast valves with by-pass channels;
- hermetic valves closed manually; and
- electromechanical antiblast devices.

IRONBARK

CSDB-3/650,080

Gravel Filter-Shock Absorber (Figure 142) is the simplest and a sufficiently effective means of damping a shock wave. The damping coefficient (the ratio of the shock wave pressure at the entrance to the shock wave pressure at the exit) depends on the magnitude of the pressure at the entrance, the thickness of the gravel layer and its density. With a layer of gravel 60cm thick the damping coefficient fluctuates within the limits of 5 to 10.

The coarseness and thickness of the layers of gravel are selected on the basis of the resistance to the flow of the air collected by the ventilator, which may be equal to a 15 to 20mm water column with manual, and a 25 to 30mm water column with mechanical operation of the ventilator.

A gravel shock absorber does not completely damp the shock wave of an atomic burst, therefore besides filter-shock absorbers, manually operated hermetic valves are installed on water lines and stove pipes in field installations.

Gravel filter-shock absorbers are used mainly for the protection of chimneys.

IRONBARK

CSDB-3/650,080

Filter Shock Absorber (Figure 143), combined with shock wave cut-off is a more improved device for damping the shock wave of an atomic burst. The cut-off reduces the shock wave action time in the shock absorber as a result of the closure* of the air intake aperture by the disc-cutoff located in the upper horizontal partition of the shock absorber, as a consequence of which such a shock absorber reduces the pressure approximately 20 times. The filter-shock absorber combined with a cutoff is used in light-type installations for the protection of ventilation apertures and chimneys.

Antiblast valves with bypass channel (Figure 144), at the moment of a burst, automatically close the ventilation or exhaust apertures by means of a piston displaced by the impact of the shock wave. The presence of a bypass channel ensures closure of the aperture before the shock wave reaches it through the bypass channel.

Figure 144. Basic Diagram of an Antiblast Valve with Bypass Channel

Closure time for the disc of the filter-shock absorber placed in a filter ventilation system equipped with filters FP-50, must be not more than $1m/sec$ where $\Delta p_{exit}^ = 0.2kg/cm^2$ and the computed pressure at entrance $\Delta p_{entrance}^{**} = 5kg/cm^2$. * $-vykh$ ** vkh

The valve, shown in Figure 147, consists of two separate elements: the valve itself and the bypass channel in the form of an elbow chamber made of steel tubes. This allows the chamber to be installed in the protective features of the installation during its construction and the valve to be installed during the equipment assembly.

Antiblast valves with bypass channels are intended principally for the protection of apertures in heavy-type defense installations.

In Figure 148 a PVK-300 valve is shown installed in a reinforced concrete installation for the protection of a ventilation aperture with a diameter of 300mm. The 2.5 meter long bypass channel of the valve is situated in the thick protective wall of the installation. The route of air movement in the installation is indicated by arrows on the sketch.

If necessary the air duct may be closed by valve and by hand.

Electromechanical antiblast devices. The automatic antiblast device APU-100 may serve as an example. It is activated by the impingement of gamma rays at the moment of an atomic burst, that is, before the arrival of the shock wave. The device consists of a gamma ray receiver (pick up), trigger circuit (control panel), activating mechanism (two valves with electromagnets) and packing box for cables, pick-up and battery.

IRONBARK

C5DB-3/650,080

The main electrical circuit of the APU-100 is shown in Figure 149. Gamma rays impinge on the pick-up, inducing an electric current in the pick-up circuit which causes a voltage drop in the resistor R producing ignition of the three-electrode gas discharge tube L. When a discharge is induced in tube L it becomes conductive and closes the power circuit to relay P. The relay discharge, and with its contacts 1 - 2 and 3 - 4 connects battery B_3 to the closing electromagnets of both activating mechanisms (Figure 150). The electromagnets retract the plunger (serdechnik) connected to a movable plate which, on moving, covers the apertures of the lattice.

Following activation of the closing electromagnets the battery is cut off.

Power for the pickup is furnished by battery B_3 (see Figure 149) and for relay P - from battery B_2 .

The device permits closing and opening of the valve by buttons (two-way switches).

Power for the electrical circuit of the device is provided from direct current sources (from dry batteries and storage batteries) or from alternating current grids through selenium rectifiers.

During an atomic burst, the automatic antiblast device operates at those distances where the pressure in the shock wave front changes from 12 to 0.1 kg/cm². At these distances the mechanical stability of all its elements is ensured.

- a. Valve with connecting cables from the control panel
- b. Valve with open aperture

The pick-up (Figure 151) is installed outside the installation in the ground at a depth of 30 to 40cm. It is constructed of a steel tube inside of which a gas counter, type STS-5, is placed. Basic dimensions of the pick-up: diameter - 6.5cm; length - 26.5cm; and weight - 5.5kg.

The pick-up is connected by flexible cable to the overall circuit of the device. By its sensitivity, the pick-up ensures dependable activation of the APU circuit with a gamma ray dose rate of 0.1r/hr.

The control panel ensures: prompt automatic activation of two valves installed in the air intake channel and chimney; closure and opening of these by two-way switches; detection of radioactive contamination inside the shelter and filter-absorbers at a radiation level of 0.1r/hr and higher.

The control panel is installed inside the shelter.

Overall activation time of the valve does not exceed 0.1 second.

The automatic antiblast device APU-100 ensures dependable protection of the filter-ventilation plant and heating system from the shock wave of an atomic burst and is designed for long-term utilization in important field defense installations.
